

# Correlates of Depression in Bipolar Disorder

Paul J. Moore\*, Max A. Little, Patrick E. McSharry, Guy M Goodwin, John R Geddes

**Abstract**—We analyze time series from 100 patients with bipolar disorder for correlates of depression symptoms. Since the sampling interval is non-uniform we quantify the extent of missing and irregular data using new measures of *compliance* and *continuity*. We find that uniformity of response is negatively correlated with the standard deviation of sleep ratings ( $\rho = -0.26, p = 0.01$ ). To investigate the correlation structure of the time series themselves, we apply the Edelson-Krolik method for correlation estimation. We examine the correlation between depression symptoms for a subset of patients and find that self-reported measures of *sleep* and *appetite/weight* show a lower average correlation than other symptoms. Using surrogate time series as a reference data set, we find no evidence that depression is correlated between patients, though we note a possible loss of information from sparse sampling.

## I. INTRODUCTION

HEALTH telemonitoring can benefit both patients and healthcare providers. A systematic review by Polisen *et al.* [1] found that home telehealth saved costs in 20 out of 22 studies, though it did note the poor quality of most of the economic evaluations. Another review by Paré *et al.* [2] examined 65 empirical studies of telemonitoring over four types of chronic illnesses: pulmonary conditions, diabetes, hypertension, and cardiovascular diseases. They drew no conclusion about economic viability but only because this was the subject of few studies most of which had no detailed analysis. However, they suggested that telemonitoring might

have a positive effect on the patients' condition and that this would be a promising avenue for research. A more recent *BMJ* review [3] found evidence of fewer hospital admissions and lower mortality among patients allocated to receive telehealth interventions, though again there was no evidence of cost savings. However there are other benefits from both the patient's and clinician's point of view. The patients are monitored in their own environment, avoiding 'white coat syndrome' and they may have the freedom to manage their own reporting.

Most obvious from the researcher's point of view is the automated acquisition of data for analysis, sampled more often than an outpatient appointment would allow. Here, though, the freedom afforded to the patient has a potential disadvantage for time series analysis. If data can be returned at any time then the analyst cannot assume a regular reporting interval. Since most time series methods require uniform sampling, a common approach is to interpolate the data as a preprocessing step. In this study we apply methods that may be used directly on non-uniform data and introduce two new measures for quantifying non-uniformity. The structure of the paper is as follows. In §II we introduce time series analysis and the Edelson-Krolik method for estimating correlation. In §III we describe measures for quantifying non-uniformity in time series and in §IV show their application to telemonitored data. §V describes several different applications of the Edelson-Krolik correlation and correlation between time series using surrogate data. Finally, §VI summarizes the findings of the study.

## II. TIME SERIES

Time series analysis involves the description, explanation and prediction of observations taken sequentially in time [4]. Description implies the use of numerical and graphical descriptive statistics such as time plots and the correlogram. Correlograms can reveal *seasonality*, which is the tendency to repeat

74 a pattern of a certain periodicity such as a yearly  
 75 cycle and *trend* or long-term variation up or down.  
 76 Whereas description provides information about a  
 77 given time series, inference induces a general form  
 78 based on a finite number of observations. An ex-  
 79 ample is time series regression which attempts to  
 80 model an underlying relationship between depen-  
 81 dent variables and time. Regression is often applied  
 82 in the context of time series prediction because of  
 83 its many practical applications. Linear approaches  
 84 are popular because they are readily interpretable  
 85 and convenient [5]. Stationary, linear time-invariant  
 86 (LTI) Gaussian systems introduce several symme-  
 87 tries that have many conveniences including statisti-  
 88 cal stability, sufficiency of 1st and 2nd-order mo-  
 89 ments, and convex and analytic inference procedures  
 90 [6]. Nonlinear models can represent regime switch-  
 91 ing behaviour and parsimonious nonlinear models  
 92 have been shown to outperform linear methods in  
 93 economic forecasting [7].

#### 94 *Correlation estimation*

95 The autocorrelation function is an important mea-  
 96 sure of serial dependence in a time series, and is  
 97 defined for a stationary random process  $Y(t)$  as

$$\rho(s) = \frac{\gamma(s)}{\gamma(0)} \quad (1)$$

98 where  $s$  is the time lag and  $\gamma(s)$  is the *autoco-*  
 99 *variance function* defined as the covariance between  
 100  $Y(t)$  and  $Y(t - s)$ . An informative way of rep-  
 101 resenting the serial dependence in a time series  
 102 is by a graph of autocorrelation coefficients  $\rho(k)$   
 103 against the integer lag  $k$ . This sequence represents  
 104 a sample autocorrelation function (a.c.f.) and is  
 105 called the *correlogram* [8]. Since natural time series  
 106 often have missing or irregular data, it is often the  
 107 applied sciences that have derived methods for their  
 108 analysis. In astrophysics Edelson and Krolik [9]  
 109 derived the discrete correlation function (DCF) for  
 110 correlation estimation in non-uniform time series. It  
 111 is defined for two discrete, centered time series  $a_i$   
 112 and  $b_j$ , first as a set of unbinned discrete correlation  
 113 values

$$UDCF_{ij} = \frac{a_i b_j}{\sqrt{(\sigma_a^2 - e_a^2)(\sigma_b^2 - e_b^2)}} \quad (2)$$

114 for a measured pair of observations  $(a_i, b_j)$  whose  
 115 time difference is  $\Delta t_{ij}$ . Here  $a_i$  and  $b_j$  are a concise

notation for  $a(t_i)$  and  $b(t_j)$  respectively,  $\sigma_a, \sigma_b$  are  
 the respective standard deviations and  $e_a, e_b$  are  
 estimates of the measurement noise in each time  
 series. The discrete correlation function is derived  
 by averaging the set of  $M$  unbinned values

$$DCF(\tau) = \frac{1}{M} \sum_{|\Delta t_{ij} - \tau| < \frac{\Delta\tau}{2}} UDCF_{ij} \quad (3)$$

where  $\tau$  is the bin centre and  $\Delta\tau$  is the bin width.  
 The standard error is given by

$$\sigma_{DCF}(\tau) = \frac{1}{M''} \left( \sum (UDCF_{ij} - DCF(\tau))^2 \right)^{1/2} \quad (4)$$

recalling that  $UDCF_{ij}$  is a set and  $DCF(\tau)$  is  
 a scalar for given  $\tau$ . The summation is over  
 $|\Delta t_{ij} - \tau| < \frac{\Delta\tau}{2}$  as before and the normalising con-  
 stant  $M''$  is equal to  $((M - 1)(M' - 1))^2$  with  $M'$   
 the number of unique measurement times for the  
 series  $a_i$ .

The Edelson-Krolik method is closely related to  
 the *variogram*, an approach that is well known in  
 geostatistics where it is used to model spatial corre-  
 lations [10]. It was until recently rarely mentioned in  
 texts on time series or in the statistical literature as  
 a whole [11] with the exception of Chatfield [4] and  
 Diggle [8], who defines the variogram as follows:

$$V(k) = \frac{1}{2} \mathbb{E}[\{Y(t) - Y(t - k)\}^2] \quad (5)$$

$$= \gamma(0) (1 - \rho(k)) \quad (6)$$

where terms are defined as before. A plot of the  
 quantities  $v_{ij} = \frac{1}{2} \{y(t_i) - y(t_j)\}^2$  for all delays  
 $k_{ij} = t_i - t_j$  is called the sample variogram. As  
 with the DCF, random scatter in the plot may arise  
 from small sample sizes used in calculating  $v_{ij}$ . This  
 scatter can be reduced by averaging  $v_{ij}$  over binned  
 time values to give  $\bar{v}(k)$ .

The binned variogram and discrete correlation  
 function are examples of a *slotting* approach that  
 uses a rectangular kernel to bin pairs of obser-  
 vations. They belong to one of four categories  
 identified by Broerson *et al.* [12] for handling non-  
 uniform data. The other categories are direct trans-  
 form approaches, such as the Lomb-Scargle (LS)  
 periodogram [13], model-based estimators (which  
 presuppose a knowledge of the time series dy-  
 namics) and resampling through interpolation. The  
 Lomb-Scargle approach, kernel methods (though  
 not slotting) and linear interpolation are compared in  
 [14]. Since the data analyzed in this study has high

156 relative noise and large gaps in the time indexes, we  
 157 apply the Edelson-Krolik slotting approach. It pro-  
 158 vides a sample correlogram directly and avoids the  
 159 assumptions necessary for interpolation or model-  
 160 based estimators.

### 161 III. MEASURES OF NON-UNIFORMITY

162 We next introduce two measures for quantifying  
 163 missing and non-uniform responses in time series.  
 164 The first, which we call *compliance* measures the  
 165 proportion of real observations in a time series  
 166 which contains imputed values. The second mea-  
 167 sure, called *continuity* quantifies the sampling reg-  
 168 ularity among those real observations. Both mea-  
 169 sures are easily derived from a uniformly sampled  
 170 series with missing data, but here we start from  
 171 an irregular series and assume that a response is  
 172 valid for an interval rather than a single point in  
 173 time. This condition would apply, for example, to  
 174 the answer from questionnaire where the relevant  
 175 interval is the week prior to the response. We begin  
 176 by considering the process of resampling the time  
 177 series into a homogenized equivalent with uniform  
 178 intervals.

#### 179 *Compliance*

180 Figure 1 illustrates the resampling process as-  
 181 suming that sampling is approximately once per  
 182 week. The optimal weekday  $w$  for the resampled  
 183 time series is chosen to minimise the total deviation  
 184 of the original responses from their corresponding  
 185 resampled position on the  $X$ -axis or ‘comb’ of  
 186 weekdays. The deviation in this case is the elapsed  
 187 time to the first response within seven days.  
 188

189 The comb is then populated from the original  
 190 series as follows. Starting from weekday  $w$  at the  
 191 start, or the last instance of  $w$  before the start, of  
 192 the time series we record any response within seven  
 193 days. We repeat the search from weekday  $w$  in the  
 194 following week and continue until the last response  
 195 of the time series is reached. If no response is found  
 196 within seven days, a missing value is imputed by  
 197 random selection from the previous four responses.  
 198 The imputed value itself is chosen for the purposes  
 199 of illustration and does not affect the non-uniformity  
 200 measures.

201 Figure 2 shows the effect of resampling on two  
 202 example series. Most of the original responses are

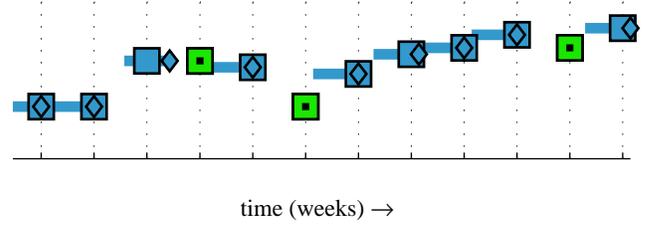

Fig. 1. Illustration of resampling. Diamond markers represent the original, non-uniform time series and the horizontal lines to the left of each marker show the period over which the response is valid. Square markers represent the resampled series and those with a square central dot are imputed values. The  $X$ -axis or ‘comb’ shows the optimal weekday which when aligned with the original series gives the minimum total distance (deviation) of the sample time from the response time.

203 not shifted while some are moved to an earlier time  
 204 point and where this cannot be accomplished, an  
 205 imputation is made.

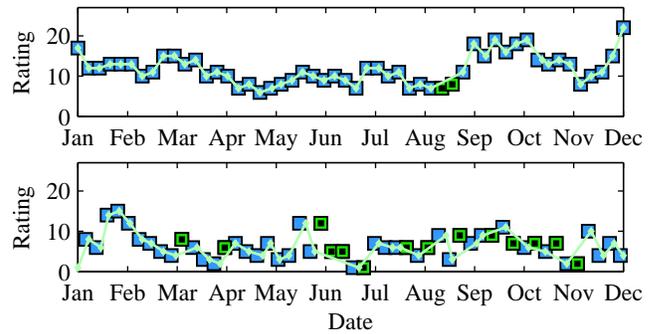

Fig. 2. Effect of resampling on high and low compliance time series. The original responses are denoted by small diamond markers and the resampled series by the larger square border. Imputed values are shown with a central square dot. The top plot represents an approximately uniform original time series in which resampling preserves the time stamps of the original responses: most diamond markers are centered in the squares. The lower plot illustrates a non-uniform series where many responses are late and some are missing. The late responses are shown by a diamond marker located to the right of center of the square border.

206 We define compliance as the proportion of non-  
 207 imputed values in the resampled time series. Im-  
 208 putations occur when a response is later than the  
 209 sample period  $\tau$  which in this application is equal  
 210 to 7 days. Formally,

$$C_m = \frac{1}{N} \sum_{k=0}^{N-1} \Theta \left[ \sum_{i=1}^{N'} \mathbf{1}[k\tau \leq t_i < (k+1)\tau] \right] \quad (7)$$

211 where  $C_m$  is compliance,  $\tau$  is the uniform sample  
 212 period and  $t_i$  is the  $i^{\text{th}}$  element of the time vector  
 213 for the original series, which has  $N'$  points.  $N$

is the number of points in the resampled series and is equal to the number of weeks spanned by the original time series, allowing for the period of validity. The function  $\Theta$  is equal to 0 if its argument is 0 otherwise it is equal to 1, and the indicator operator  $\mathbf{1}$  has value 1 for a boolean argument of `true` and 0 for `false`. The value of  $C_m$  lies between 0 and 1.

As long as the original series covers all the new sample time points, there will be no imputations and the compliance is 100%. For example if responses are returned more often than every week, a uniform series may be derived by discarding some responses and without loss of compliance. A non-uniform series may also exhibit full compliance as long as no response is more than six (more generally,  $\tau - 1$ ) days late. However, longer gaps result in an imputed value being added to the uniform series and compliance being reduced. The measure thus penalizes missing data but not additions or late returns.

### Continuity

A low compliance implies that there is a large proportion of imputed points in the resampled series but gives no information about their distribution throughout the observed responses. A second measure which we call *continuity* measures the connectedness of non-imputed responses in the resampled time series. To develop the measure, we examine the sequence of points in the resampled series and label them with a state indicator of  $\mathbb{P}$  for imputed and  $\mathbb{R}$  for not imputed. The number of sequential state changes  $\mathbb{R} \rightarrow \mathbb{P}$  is a count of the discontinuity and we use the ratio of this count to  $N_r - 1$ , where  $N_r$  is the number of  $\mathbb{R}$  states. A simple example is the sequence  $\mathbb{R}\mathbb{R}\mathbb{R}\mathbb{P}\mathbb{P}\mathbb{R}\mathbb{P}\mathbb{P}\mathbb{R}$ . Here there are 2 sequential changes of state from  $\mathbb{R}$  to  $\mathbb{P}$  out of a total of five  $\mathbb{R}$  states giving a continuity of  $2/4$ . The sequence  $\mathbb{R}\mathbb{R}\mathbb{R}\mathbb{R}\mathbb{R}$  then has a continuity of 1, and the sequence  $\mathbb{R}\mathbb{P}\mathbb{R}\mathbb{P}\mathbb{R}$  has a continuity of 0. In general we then have

$$C_t = 1 - \frac{1}{N_r - 1} \left( \sum_{k=1}^{N-1} \mathbf{1}[(w_k, w_{k+1}) = (\mathbb{R}, \mathbb{P})] \right) \quad (8)$$

where  $C_t$  is continuity,  $N$  is the length of the resampled series and  $w_k \in \{\mathbb{R}, \mathbb{P}\}$  is the state of the  $k^{\text{th}}$  data point. The minimum possible continuity

occurs when the  $\mathbb{P}$  states are distributed singly throughout the time series. In this case,

$$C_{t(\min)} = 1 - \frac{N_p}{N - N_p - 1} \quad (9)$$

$$\approx \begin{cases} \frac{2C_m - 1}{C_m} & \text{if } C_m \geq 0.5 \\ 0 & \text{otherwise} \end{cases} \quad (10)$$

for  $N \gg 1$  where  $N_p$  is the number of  $\mathbb{P}$  states. It can be seen from (10) that as the compliance approaches 1, the minimum possible continuity approaches the compliance.

So compliance is the proportion of non-imputed responses and continuity is the proportion of correct intervals among them. Continuity summarizes the interval distribution using the probability density located only at the desired interval. The location of the remaining mass, corresponding to the distribution shape, does not influence its value.

This approach gives an advantage over standard dispersion measures (of either the raw or the homogenized series) because all intervals longer than the sampling period are classed together. Long gaps in the time series, when the patient fails to respond for a period, do not greatly influence the continuity value, although they are reflected in the compliance. The property is also relevant to the autocorrelation calculation because time series with high continuity can be treated as uniform for this purpose. Both compliance and continuity can be useful in both selection of near-uniform series for the application of standard methods and for exploring non-uniformity as an informative property in itself.

## IV. APPLICATION OF MEASURES

We apply the measures to time series from 153 patients with bipolar disorder who were monitored between 2006 and 2011. Data were collected as part of the OXTEXT programme funded by the National Institute for Health Research which investigates the potential benefits of self monitoring of mood for people with bipolar disorder. The sub-sample of participants in this study was selected from the OXTEXT cohort, and includes those patients who had used the mood monitoring prior to recruitment into OXTEXT and who had given consent for the use of anonymised retrospective data for exploratory time series analysis.

301 The mood data is returned approximately each  
 302 week and comprises answers to standard self-rating  
 303 questionnaires for both depression and mania. The  
 304 rating scale used for depression is the *Quick Inven-*  
 305 *tory of Depressive Symptomatology - Self Report*  
 306 (*QIDS-SR<sub>16</sub>*) [15] which has 16 questions covering  
 307 nine symptom domains for depression (Diagnostic  
 308 and Statistical Manual of Mental Disorders, 4th  
 309 edition, Text Revision) [16]. This self-rated instru-  
 310 ment has highly acceptable psychometric proper-  
 311 ties, including high validity [17]. Each domain can  
 312 contribute up to 3 points giving a total possible  
 313 score of 27 on the scale. The severity of mania is  
 314 quantified using the *Altman Self-Rating Mania Scale*  
 315 (*ASRM*) [18] which has 5 questions, each of which  
 316 can contribute up to 4 points, giving a total possible  
 317 score of 20.

### 318 A. Data selection

319 The initial set of 153 patients is first cleaned by  
 320 removing repeated response values, that is those  
 321 which share the same time stamp. These repeats  
 322 arise when a patient resubmits a rating score either  
 323 by mistake or in order to correct an earlier response.  
 324 Assuming that earlier values are being corrected,  
 325 we remove repeated responses by taking the most  
 326 recent in the sequence. We then create Set A ( $n=93$ )  
 327 with members whose time series have at least 25  
 328 data points, or approximately six months duration.  
 329 Figure 3 illustrates the data selection process.

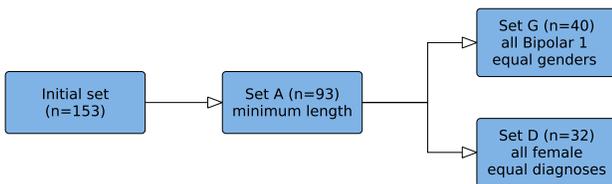

Fig. 3. Flow chart for data selection. From the initial data set, Set A ( $n=93$ ) of time series having a minimum length of 25 data points is selected. Two further subsets are then selected from Set A. Set G ( $n=40$ ) has equal numbers of each gender, all with a diagnosis of Bipolar I disorder. Set D ( $n=32$ ) has equal numbers of patients having Bipolar I and Bipolar II diagnoses, all of whom are female. The selection algorithm matches patients by time series length. Where no patient of matching length can be found, the range is progressively widened until one or more matches is found.

330 Two further subsets are then created from Set  
 331 A, one having equal numbers of male and female  
 332 patients and a second with equal number of Bipolar  
 333 I (BPI) and Bipolar II (BP II) diagnoses. The first

subset is labelled as Set G ( $n=40$ ) and contains  
 334 patients all of whom have a diagnosis of BPI  
 335 disorder. It is created by selecting all the patients  
 336 with BPI from Set A and removing the female  
 337 patient with the shortest time series length. The  
 338 second subset, labelled Set D ( $n=32$ ), has equal  
 339 numbers of patients diagnosed with BPI and BP II  
 340 disorder, all of whom are female. Set D is created  
 341 by retaining the 16 female BP II patients from Set A  
 342 and selecting 16 BPI female patients to match for  
 343 time series length. The selection algorithm attempts  
 344 to match the length for each individual patient by  
 345 progressively widening the search range until a  
 346 suitable match is found. Descriptive statistics of the  
 347 subsets are given in the electronic supplementary  
 348 material §I.  
 349

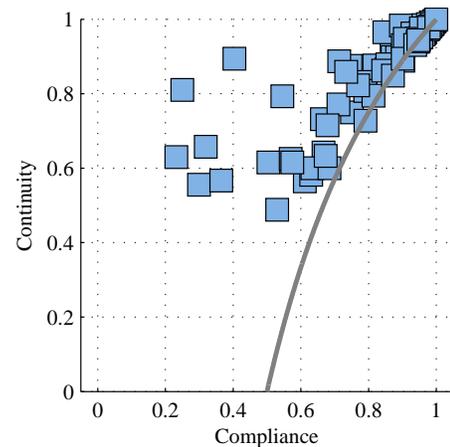

Fig. 4. Scatter plot of continuity against compliance for patients having at least 25 points in their time series ( $n=93$ ). The approximate minimum continuity limit  $2 - C_m^{-1}$  from (10) is shown as a line. There are some short time series which have continuity values slightly lower than this limit. As compliance tends towards 1, the minimum possible continuity tends towards compliance. Those series in the upper left of the plot with high continuity and low compliance have large gaps where there is a long sequence of imputed points.

### Non-uniformity

350 Using the subset of data labelled Set A, we  
 351 derive the compliance and continuity measures for  
 352 each patient. A scatter plot is shown in Figure 4.  
 353 From (10) we see that the minimum continuity  
 354 tends towards the compliance as the compliance  
 355 approaches 1. For lower compliance where there is  
 356 a higher proportion of imputations, the continuity is  
 357 more dispersed.  
 358

359 For the next analysis, we assume that any text  
 360 message latency is small in comparison with the

361 patient's delay in responding to a prompt from  
 362 the monitoring system. We do not know when the  
 363 prompt message is received by the patient so we  
 364 cannot distinguish total network latency from the  
 365 patient's response delay. However since the prompt  
 366 messages are dispatched at weekly intervals, we can  
 367 judge the scale of the overall delays by examining  
 368 the time between prompt and receipt. The analysis  
 369 is provided in electronic supplementary material §V  
 370 and shows that most patients have a mean delay  
 371 of half of one day or more. This result is expected  
 372 because the questionnaire relates to a weekly period  
 373 rather than an instant in time: patients do not have  
 374 to reply to the prompt immediately. However, the  
 375 network delay remains unknown and a quantitative  
 376 study of the monitoring infrastructure would be  
 377 valuable in determining the scale and nature of  
 378 network latency.

### 379 *Demographic and mood data*

380 We examine the correlation between continuity  
 381 and both demographic and mood data over the set of  
 382 patients using Set G ( $n=40$ ) which has equal num-  
 383 bers of male and female patients and Set D ( $n=32$ )  
 384 with equal numbers of Bipolar I (BPI) and Bipolar II  
 385 (BPII) diagnoses. No pattern emerges in either case,  
 386 and a two-sample Kolmogorov-Smirnov test does  
 387 not distinguish the distribution of male vs female  
 388 or BPI vs. BPII non-uniformity measures. Further  
 389 details can be found in the electronic supplementary  
 390 material §IV.

391 Next we look for correlates of non-uniformity  
 392 with mood. There are 9 variables for depression  
 393 corresponding to symptoms of sleep, appetite etc.,  
 394 and 5 variables for mania which we summarize for  
 395 each patient by mean, standard deviation and mean  
 396 absolute difference. We take the rank correlation for  
 397 each symptom with continuity over the set of 93  
 398 patients in Set A. The results are shown in Table I.  
 399 No correlations were found between mean symptom  
 400 levels and continuity. For the dispersion statistics  
 401 only sleep in the depression questionnaire was found  
 402 to have a correlation significant at the 1% level.

403 Variability of sleep correlates negatively with  
 404 continuity when measured by standard deviation  
 405 ( $\rho=-0.26$ ,  $p=0.01$ ) and mean absolute difference  
 406 between sequential values ( $\rho=-0.25$ ,  $p=0.02$ ). A  
 407 similar result was found when using compliance as  
 408 the non-uniformity measure. The scatter plots for

Domain	Mean	Variability measure	
		Std. dev.	Mean abs. diff.
Sleep	+0.14 (0.18)	-0.26 (0.01)	-0.25 (0.02)
Feeling sad	-0.13 (0.21)	-0.17 (0.10)	-0.09 (0.39)
Appetite/wt	-0.06 (0.59)	-0.04 (0.75)	-0.02 (0.88)
Concentration	-0.12 (0.24)	+0.01 (0.94)	-0.00 (0.96)
Self-view	-0.13 (0.22)	-0.15 (0.14)	-0.13 (0.23)
Death/suicide	-0.11 (0.27)	-0.15 (0.16)	-0.19 (0.06)
Gen. interest	-0.11 (0.29)	-0.16 (0.12)	-0.19 (0.07)
Energy level	-0.08 (0.43)	-0.14 (0.19)	-0.05 (0.61)
Slowed down	-0.09 (0.39)	-0.08 (0.45)	-0.01 (0.91)

TABLE I  
 RANK CORRELATION ( $p$ -VALUES) BETWEEN DEPRESSION  
 SYMPTOMS AND CONTINUITY FOR SET A.

both statistics are shown in Figure 5. 409

We note that there will be a sampling distribution 410  
 for both the mean and variability measures arising 411  
 from the limited sample sizes, which would mani- 412  
 fest in Figure 5 as a range for each point. 413

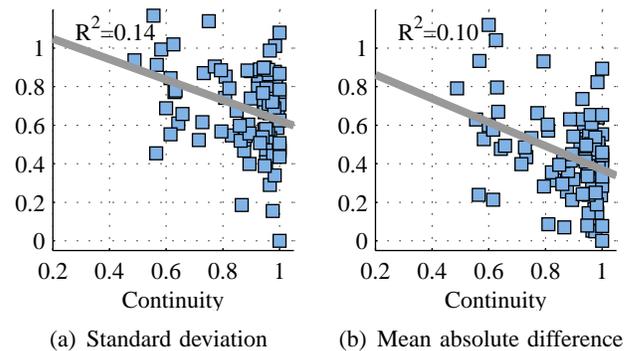

Fig. 5. Scatter plots for sleep against continuity. In (a) the standard deviation of all the resampled sleep values (excluding imputed points) for each patient are plotted against the continuity score for that patient. In (b) the mean of the absolute difference between sequential resampled values, again ignoring imputed points, is used. For both cases, patients with lower continuity show a higher variability in sleep responses on average. The linear least-squares fit is marked as a line.

414 For some symptoms, any correlation with non- 415  
 uniformity might be hidden by this effect. However, 416  
 since the same sampling limits apply to all symp- 417  
 toms we can distinguish sleep variability as having 418  
 a relatively strong association with non-uniformity 419  
 of response.

420 The relation of non-uniformity of response with 421  
 sleep variability is an important finding from this 422  
 analysis. The association is also interesting if re- 423  
 sponse uniformity is taken as an indicator of gen- 424  
 eral functioning. We would expect that delays in

425 responding are caused by holidays, work commit-  
 426 ments, physical illness, forgetting to reply, a low  
 427 priority for replying or chaotic behaviour. Psycho-  
 428 logical factors may have an influence and several  
 429 of the symptoms explicitly measured on the QIDS  
 430 scale are relevant, in particular severe lassitude or  
 431 lack of energy, a lack of interest, poor concentration,  
 432 and thoughts of death/suicide. As pointed out, it is  
 433 quite possible that correlations with these variables  
 434 exist but that they are below the noise threshold.  
 435 The relatively stronger effect of sleep points to a  
 436 number of possibilities. Firstly, a strong association  
 437 between sleep and mental illness is well established,  
 438 if not well understood [19]. So one possibility is that  
 439 sleep is simply the strongest indicator of an under-  
 440 lying disorder which causes irregularity through the  
 441 behavioural issues listed above. The causation might  
 442 be more direct, for example sleep causing problems  
 443 with memory or other functioning, leading to lost  
 444 or delayed ratings. However, it is a high variability  
 445 of sleep ratings rather than a high mean rating that  
 446 predicts non-uniformity of response. It may be that  
 447 there is some adaptation to poor sleep, whereas  
 448 inconsistent sleep leads to inconsistent behaviour.  
 449 The data is too noisy and does not provide a strong  
 450 enough effect to distinguish these scenarios.

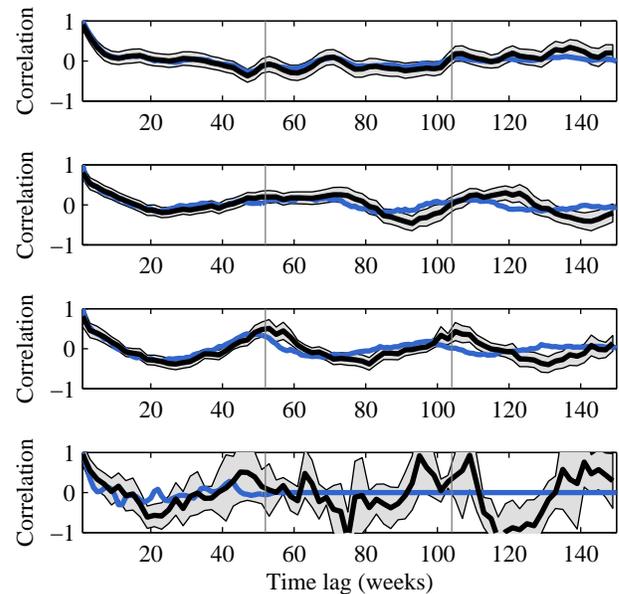

## 451 V. APPLICATION OF METHODS

452 We now apply the Edelson-Krolik method to cal-  
 453 culate autocorrelation and correlation using the time  
 454 series for depression. We first examine evidence  
 455 of seasonality from the correlogram for individual  
 456 patients. We then look at the correlation between  
 457 symptoms of depression and finally apply a surro-  
 458 gate data method to detect correlations among the  
 459 set of time series themselves.

### 460 *Seasonality*

461 We examine the autocorrelation function of the  
 462 depression time series using the Edelson-Krolik  
 463 method to determine the autocorrelation at succes-  
 464 sive lags. Four examples of correlograms are shown  
 465 in Figure 6 in comparison with a standard correlo-  
 466 gram (lighter line) which has not been adjusted for  
 467 non-uniform response times. The third plot from the  
 468 top shows a yearly seasonality for both the Edelson-  
 469 Krolik method and the unadjusted correlogram with  
 470 the latter having a peak correlation at less than 50  
 471 weeks and less seasonal variation.

472 Figure 7 is the Lomb-Scargle periodogram cor-  
 473 responding to this time plot. It shows a peak of  
 474 spectral power at 370 days indicating a yearly  
 475 seasonality. The depression time series do not in  
 476 general show clear evidence of yearly periodicity,  
 477 though some have a peak at or near this period.  
 478 Most exhibit a rapid decrease in correlation with  
 479 lag and some show evidence of a trend, indicated  
 480 by the correlogram not tending to zero as the lag  
 481 increases.

482 Fig. 6. Correlograms for the depression time series from four  
 483 patients. In each plot, the dark line is the correlogram estimated using  
 484 the Edelson-Krolik method with a bin width of 2 weeks and showing  
 485 two standard errors each side as a filled region. The lighter line is the  
 486 autocorrelation calculated under the assumption of a uniform series.  
 487 Imputed points are not used in either calculation. In the time plot  
 488 third from the top there is clear evidence of yearly seasonality of  
 489 depression. The continuity values for the time series are, from top to  
 490 bottom: 0.99, 0.92, 0.87 and 0.30. Vertical lines are year markers  
 491 corresponding to 52 and 104 weeks. Note that correlograms are  
 defined only at integer lags or bin centres but are shown as continuous  
 lines for clarity.

### 482 *Correlation between depression symptoms*

483 The correlation between depression symptoms is  
 484 examined for patients who have at least 100 data  
 485 points in their homogenized time series. The first  
 486 100 responses are taken, the imputed values re-  
 487 moved and the means subtracted from the individual  
 488 domain scores. Correlation between domains is then  
 489 calculated using the Edelson-Krolik method (3) and  
 490 the scores averaged over the set of patients. In  
 491 order to provide a comparison between symptoms,

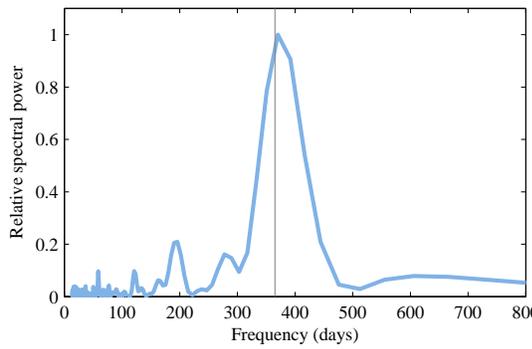

Fig. 7. Lomb periodogram for a patient exhibiting seasonality of depression. The corresponding correlogram in Fig. 6 is third from the top. The spectral power is normalised by the peak power and the periodicity of 365 days is marked as a vertical line. The peak is at a period of 370 days and a second much smaller peak occurs at 196 days. In general the depression time series do not show such clear evidence of yearly periodicity, although some patients have a peak at or near this period.

492 only those patients with non-zero symptom series  
 493 and positive correlations are selected. There are 6  
 494 patients showing some pairs of negative correlations  
 495 but these did not show any common relationship.  
 496 The subset of patients fulfilling these criteria is de-  
 497 noted Set E and its statistical properties are summa-  
 498 rized in the electronic supplementary material §II,  
 499 with further details about selection. The selection of  
 500 Set E is illustrated in Figure 8.

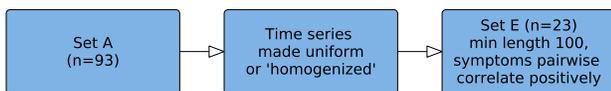

Fig. 8. Flow chart for data selection. From Set A ( $n=93$ ), a homogenized set of time series is created and from this Set E ( $n=23$ ) is selected. It has at least 100 data points in the homogenized time series, and all the symptom time series for a patient have positive pairwise correlations.

501 A heat map showing the relationship between  
 502 symptom domains is shown in Figure 9.

503 On average, the symptom domains *Sleep* and  
 504 *Appetite/weight* correlate less than other domains.  
 505 By contrast *Feeling sad* correlates strongly with  
 506 other domains while *Slowed down/restless* shows  
 507 less correlation with others.

508 An analysis of the autocorrelation structure for  
 509 symptom time series explains why the symptoms  
 510 of *Sleep* and *Appetite/weight* tend to correlate less  
 511 when paired with other domains. We take the 23  
 512 time series used above and find the autocorrelation  
 513 at using the Edelson-Krolik method on the homoge-

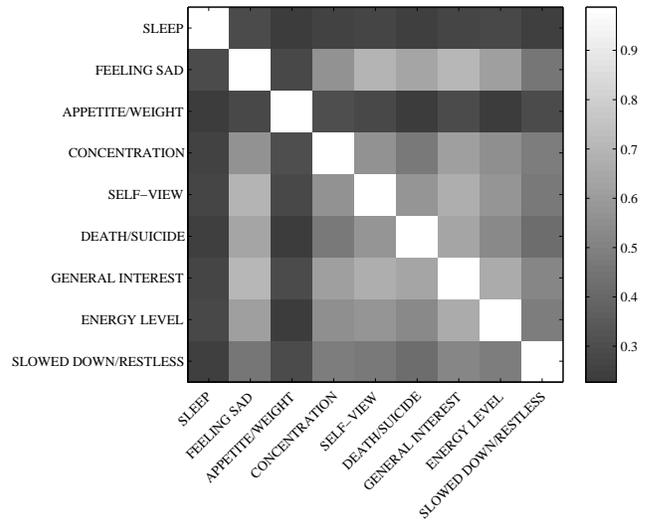

Fig. 9. Matrix of mean correlation between pairs of depression symptoms. For each patient in a set of 23, we find the correlation between pairs of symptoms and present the average over whole set. Only positive correlations greater than two standard errors from zero are used and patients with negative correlations or non-significant autocorrelations are excluded. The white diagonal represents the zero lag autocorrelations of individual domain time series.

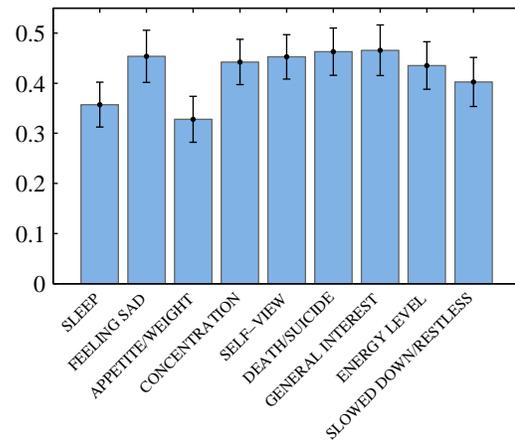

Fig. 10. Autocorrelation for symptom time series. The chart represents the mean first order autocorrelation of a set of 23 patients, with error bars showing the standard error. The symptoms *Sleep* and *Appetite/weight* have a lower autocorrelation than the rest implying a low relative correlation with symptoms which have a different autocorrelation structure.

nized time series with imputed points removed. The results are shown in Figure 10. The symptoms *Sleep* and *Appetite/weight* have a lower autocorrelation than the other symptoms which explains their relatively low pairwise correlation in Figure 9. Although *Sleep* and *Appetite/weight* have a similar first order autocorrelation, Figure 9 shows that they do not themselves correlate as a pair, the reason being that their autocorrelation structure is somewhat different:

523 the autocorrelation for *Sleep* remains higher than  
 524 *Appetite/weight* as the lag increases. Autocorrelation  
 525 coefficients up to a lag of 4 are shown in the  
 526 electronic supplementary material §III.

527 We note that these two symptoms are the most  
 528 amenable to objective measurement out of the  
 529 nine symptoms in the QIDS rating scale and that  
 530 *Slowed down/Restless*, which might also fall into  
 531 this category also correlates less than the others.  
 532 It may be that the other symptoms: *Feeling sad*,  
 533 *Concentration*, *Self-view*, *Thoughts of death/suicide*,  
 534 *Interest* and *Energy level* have a common factor  
 535 which influences them more than it does the other  
 536 three symptoms. This finding is similar to that in  
 537 [20] which identified three factors in the IDS instru-  
 538 ment: cognitive/mood, anxiety/arousal and sleep (or  
 539 sleep/appetite for the self-rated instrument).

#### 540 Time series correlation

541 In this section, we look for similar mood changes  
 542 in patients by examining pairwise correlations be-  
 543 tween their time series of depression ratings. We  
 544 take a set of 28 patients who have complete depres-  
 545 sion series during the years 2009 and 2010 which  
 546 we denote as Set F.

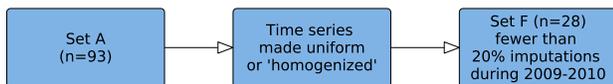

Fig. 11. Flow chart for data selection. From Set A ( $n=93$ ), a homogenized set of time series is created and from this Set F ( $n=28$ ) is selected. It is comprised of time series which span the years 2009-2010 and have fewer than 20% of imputed points over that period.

547 The selection process is illustrated in Figure 11  
 548 and descriptive statistics are given in the electronic  
 549 supplementary material §II. We create a reference  
 550 set of surrogate time series by shuffling the time  
 551 order of existing series while maintaining their  
 552 mean, variance and autocorrelation function. The  
 553 algorithm used for this process is described in [21]  
 554 and is implemented using the *TISEAN* function  
 555 surrogates [22]. The distribution of the pairwise  
 556 correlations for both the original and surrogate data  
 557 sets is shown in Figure 12.

558 The correlations between time series for original  
 559 and surrogate data sets appear to have the same  
 560 distribution and a two sample Kolmogorov-Smirnov  
 561 test returns a value of  $p=0.53$ . Although external

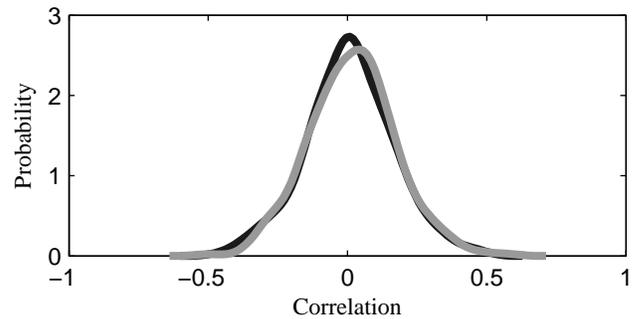

Fig. 12. Kernel density estimate of pairwise correlations between time series. The dark line is the density estimate for the original set of time series and the light line for the surrogate data. Each surrogate time series is derived from its original counterpart by taking the Fourier transform and randomizing the phases to obtain a time series with the same power spectrum. The method removes any correlation between pairs of time series that arises from a common source rather than by chance. The similarity of the distributions shows that in general there is no correlation present among pairs of the original time series.

factors do not appear to have a strong influence on  
 depression over the set of patients, this does not  
 preclude the possibility that there may be strong  
 environmental effects in individual cases.

## VI. CONCLUSION

We have addressed the problem of describing and  
 modelling time series with missing or irregularly  
 spaced values. Two new measures for quantifying  
 missing and non-uniform data were introduced and  
 applied to a database of telemonitored mood data.  
 The quantification of non-uniformity can be useful  
 in 1) investigation of non-uniformity as correlate of  
 other variables 2) selecting subsets of data where  
 uniformity is a requirement 3) use as supplementary  
 information for a clinician. We found that time  
 series uniformity does not correlate with either  
 gender or diagnostic subtype. However, variability  
 of sleep correlates with continuity. This finding has  
 implications for selecting time series according to  
 their uniformity since it may exclude patients with  
 more variable sleep ratings.

The Edelson-Krolik method uses relative dis-  
 tances rather than fixed lags to determine time  
 series correlation and so it is robust to non-uniform  
 sampling intervals. We used the method to generate  
 correlograms of depression ratings and showed that  
 one patient exhibited mood with yearly seasonality.  
 Most patients do not show evidence of seasonality,  
 but rather a short term autocorrelation structure.

We examined correlations between depression

592 symptoms and found that *sleep* and *appetite/weight*  
 593 show a lower average correlation than other symp-  
 594 toms. We found evidence that the autocorrelation  
 595 structure for these domains is different from that  
 596 of the others. Finally, we examined correlations  
 597 between patients' depression time series but found  
 598 no evidence of correlation in general. We note  
 599 that for some patients, the weekly sampling will  
 600 be below the Nyquist frequency for depression, so  
 601 information will be lost. A study identifying the  
 602 range of frequencies in depression in bipolar would  
 603 therefore help in choosing an optimal sample rate,  
 604 consistent with practical considerations.
